A broad-spectrum *mer* operon in a multi-drug resistant strain of the fish pathogen,
Aeromonas salmonicida.

Erin Parry
Colby College Biology Department
Honors Thesis
Submitted May 17, 2006

Abstract

Aeromonas salmonicida AS03, a potential fish pathogen, was isolated from

Atlantic salmon, *Salmo salar*, in 2003. This strain was found to be resistant to ≥1000 mM

$HgCl_2$ and ≥32 mM phenylmercuric acetate as well as multiple antimicrobials. Mercury

(Hg) and antibiotic resistance genes are often located on the same mobile genetic

elements, so the genetic determinants of both resistances and the possibility of horizontal

gene transfer were examined. Specific PCR primers were used to amplify and sequence

distinctive regions of the *mer* operon. *A. salmonicida* AS03 was found to have a

pDU1358-like broad-spectrum *mer* operon, containing *merB* as well as *merA, merD,*

merP, merR and *merT*, most similar to Klebsiella *pneumonaie* plasmid pRMH760. To our

knowledge, the *mer* operon has never before been documented in Aeromonas spp. PCR

and gene sequencing were used to identify class 1 integron associated antibiotic

resistance determinants and the Tet A tetracycline resistance gene. The transposase and

resolvase genes of Tn*1696* were identified through PCR and sequencing with Tn*21*

specific PCR primers. We provide phenotypic and genotypic evidence that the *mer*

operon, the aforementioned antibiotic resistances, and the Tn*1696* transposition module

are located on a single plasmid or conjugative transposon that can be transferred to *E. coli*

DH5α through conjugation in the presence of low level Hg and absence of any antibiotic

selective pressure. Additionally, the presence of low-level Hg or chloramphenicol in the

mating media was found to stimulate conjugation, significantly increasing the transfer

30   frequency of conjugation above the transfer frequency measured with mating media

lacking both antibiotics and Hg. This research demonstrates that mercury indirectly

32   selects for the dissemination of the antibiotic resistance genes of *A. salmonicida* AS03.

Introduction

34   *Aeromonas salmonicida*, a common fish pathogen, is the bacterium responsible

for furunculosis in temperate and coldwater salmonid fish (1, 36). Outbreaks of this

36   pathogen can be controlled by vaccination or, more commonly, by antibiotic

administration. However, excessive usage of antibiotics in fish feed has caused the

38   emergence of multiply antibiotic resistant fish pathogens (36). As a result of these multi-

drug resistant fish pathogens, countries such as Denmark, Norway, Sweden, and the

40   United Kingdom have begun to monitor antibiotic usage in fish farms (36). The

acquisition of antibiotic resistance genes by *A. salmonicida* confounds disease control

42   and is thus economically costly to the aquaculture industry(35). Mobile genetic elements

such as Tn*1721* and class 1 integrons isolated from *A. salmonicida* strains are commonly

44   located on resistance plasmids (36). Aeromonad resistance plasmids are often IncU

plasmids or genetically similar to IncU plasmids, suggesting that they share a common

46   origin and have since diverged due to different selective pressures(9, 37). IncU plasmids

belong to the plasmid incompatibility group U, which consists of similar plasmids that

48   cannot co-exist in any bacterial strain and are thus said to be incompatible (37) Therefore,

the resistance determinants associated with fish farm pathogens are of further

50   significance because they are very similar to those found in pathogenic enterobacteria in

humans and hospital effluents (37). Antibiotic resistances associated with resistance

52 plasmids, such as oxytetracycline resistance, have been transferred from *Aeromonas sp.*

to other bacterial species, including *E. coli* (11).

54 Mercury (Hg) resistance is prevalent among environmental bacterial isolates due

to the selective pressure of elevated mercury contamination (3). The most common

56 mechanism for bacterial mercury resistance involves the reduction of toxic mercury(II) to

volatile Hg(0) by the mercuric reductase enzyme (3, 4). The gene encoding mercuric

58 reductase, *merA*, is usually located in the *mer* operon, where it is associated with other

genes coordinating mercury resistance. In addition to *merA*, the typical *mer* operon

60 contains two genes responsible for mercury transport into the cell (*merT* and *merP*) and

two regulatory genes (*merD* and *merR*). Some *mer* operons also contain the accessory

62 genes *merB*, *merC* and *merF* (25). Since mercury resistance determinants are often

located on mobile genetic elements such as plasmids and transposons, the *mer* operon can

64 be transferred between species (3, 43). Several studies have demonstrated the transfer of

mercury resistance via conjugation between bacterial species(3, 43). Although excessive

66 antibiotic usage is largely responsible for the growing prevalence of antibiotic resistance,

non-antibiotic selective agents, including mercury and other heavy metals, have been

68 implicated as potential vehicles for the indirect selection of antibiotic resistance (34).

Antibiotic and mercury resistance genes are frequently adjacent to each other on mobile

70 genetic elements and furthermore located the same integrons (5, 28, 38, 43). This

correlation between antibiotic and mercury resistance has been documented in the fecal

72 and intestinal bacteria of primates with mercury amalgam fillings, where bacteria

containing a *mer* operon are more likely to exhibit multiple antibiotic resistance(38).

74 Furthermore, McArthur and Tuckfield observed increased antibiotic resistance in

bacterial strains exhibiting mercury resistance isolated from the sediment of mercury-

76   polluted streams (28). Although many plasmid-borne antibiotic resistant genes have been

characterized in *Aeromonas sp.*, no aeromonad to our knowledge has been documented to

78   contain the *mer* operon conferring mercury resistance (1, 36).

Class 1 integrons, which are often found in close proximity to *mer* operons, are

80   found in many gram-negative clinical isolates and have been shown to carry a high

diversity of antibiotic resistance cassettes Class 1 integrons have been documented to

82   associate with transposons encoding both mercury and tetracycline resistance, thus

mobilizing the integron and the transposon's resistance determinants together (27, 30).

84   The genes encoding class 1 integrases associated with transposons carrying mercury

resistance are identical to those encoding integrases not associated with transposons,

86   suggesting that the incorporation of integrons into transposons occurred recently and is an

ongoing process (15). Integron-borne antimicrobial resistances could therefore be easily

88   spread to pathogenic bacteria via transposons, especially with the indirect selective

pressure exerted by mercury (30).

90   The bacterial strain characterized in this study, *A. salmonicida* AS03, was isolated

from hatchery-grown Atlantic salmon, *Salmo salar* in 2003. *A. salmonicida AS03* was

92   screened for resistance to $HgCl_2$, phenylmercuric acetate (PMA), and a total of 26

antimicrobial agents. Distinctive regions of the *mer* operon, class 1 integron genes, and

94   *Tet* A, a tetracycline resistance determinant typical of many multiple-drug resistant

aeromonads isolated from aquaculture facilities, were partially characterized

96   genotypically. We provide evidence that the *mer* operon and multiple antibiotic

resistance genes in *A. salmonicida* AS03 can be concomitantly transferred to *Escherichia*

98   *coli* DH5α by conjugation and are, therefore, associated with at least one mobile genetic

element. Furthermore, low levels of either mercury or the antibiotic chloramphenicol

100   stimulated higher transfer frequencies of conjugation.

Materials and Methods

102   **Bacterial isolates and cultivation conditions.** An isolate of *Aeromonas salmonicida*,

designated strain AS03, was found to be resistant to both mercury and antimicrobials.

104   Strain AS03 was isolated from 7 of 60 Atlantic salmon (*Salmo salar* L.) during a routine

health inspection in 2003 of hatcheries in Northeastern North America. *Escherichia coli*

106   DH5α (Invitrogen Life Technologies, Carlsbad, CA) was used as the recipient in the

conjugation experiments. *A. salmonicida* AS03 and E. coli DH5α were grown on Brain

108   Heart Infusion (BHI) agar (Difco, Detroit, MI) at 22°C and at 37°C, respectively. Both

strains were stored in BHI broth with 50% (vol/vol) glycerol at -80°C.

110   **Genomic DNA extraction and confirmation of strain identity**. 16S rRNA gene

sequencing was done to confirm the identity of the *A. salmonicida* AS03 strain. Total

112   genomic DNA was extracted (E.N.Z.A. Bacterial DNA Kit, Omega Bio-tek, Doraville,

GA) according to the manufacturer's protocol. A hypervariable, 174-200 bp region of the

114   16S rDNA gene was PCR amplified using primers and cycling conditions described by

Muzyer *et al*(29) and sequenced on an ABI Prism 310 Genetic Analyzer (Applied

116   Biosystems, Foster City, CA). Isolate identification was based on 16S rDNA sequence

similarities (Blastn against GenBank at http://www.ncbi.nlm.nih.gov/BLAST).

118   **Mercury minimum inhibitory concentrations (MICs).** Hg MIC values for both $HgCl_2$

and phenylmercuric acetate (PMA; Sigma-Aldrich, Inc., St.Louis, MO) were determined

120   for *A. salmonicida* AS03 and *E. coli* DH5α by the method of Wang et al.(42) using BHI

plating media solidified with Noble agar (Difco, Sparks, MD). Bacterial suspensions (4

122 .0 µl; 2.0 McFarland) of fresh (24-48 hr) solid plating media cultures in sterile,

demineralized water were inoculated on BHI plating media containing 0, 50, 100, 250,

124 500, 750, and 1000 µM HgCl$_2$, and BHI plating media containing 0, 0.5, 1.0, 2.0, 4.0,

8.0, 16.0 and 32.0 µM PMA and incubated for two days at 22°C. Hg MICs were recorded

126 as the lowest concentration of Hg that inhibited bacterial growth. Two control strains,

mercury-susceptible *Bacillus subtilis* 168 and mercury-resistant *E. coli* SK1592, were run

128 in parallel with the experimental strains(18)

Antibiotic MICs. The *in vitro* activity of antimicrobial agents against *A. salmonicida*

130 AS03 and *E. coli* DH5α isolates was assessed by the MIC method following the National

Committee for Clinical Laboratory Standards (NCCLS) guidelines. MICs were

132 determined using the Sensititre$^®$ (MJ Panel; Trek Diagnostic Systems, Westlake, OH)

dried susceptibility panels.   Manufacturer's instructions were followed for *E. coli* DH5α,

134 however, modifications for *A. salmonicida* AS03 included incubation at 22°C for 48h.

Antibiotic MIC assays were done in triplicate for each strain, and MIC was determined as

136 the lowest concentration of the antimicrobial agent able to inhibit growth. As

recommended by NCCLS and Sensititre$^®$ guidelines, the following reference strains were

138 included as internal standards: *Escherichia coli* (ATCC 25922), *Pseudomonas*

aeruginosa (ATCC 27853), and *Enterococcus faecalis* (ATCC 29212). For specific

140 antimicrobials that were not included in the Sensititre MJ panel, additional susceptibility

testing was performed on BHI plating media with antimicrobial discs containing

142 streptomycin (10 µg), tobramycin (10 µg), kanamycin (30 µg) and chloramphenicol (30

µg) (Sensi-Disc; Becton, Dickinson and Co., Sparks, MD). *A. salmonicida* cultures were

144 incubated at 22°C while *E. coli* cultures were incubated at 37°C before zones of

inhibition were measured.

146 **PCR amplification and sequencing of *mer* genes**. Primers (Table 1) were used to probe

for and amplify regions of the *mer* operon using genomic DNA as a template (25). The

148 short (288 bp) *merA* PCR product was cloned according to the manufacturer's protocol

(TA Cloning Kit ; Invitrogen Life Technologies, Carlsbad, Calif.) and sequenced. All

150 other PCR products were cleaned (E.N.Z.A. CyclepureKit or E.Z.N.A Gel Extraction Kit;

Omega Bio-tek, Doraville, GA) according to manufacturer's protocol and sequenced. All

152 *mer* sequences were collected and aligned in Sequencher 4.6 (Gene Codes Corporation,

Ann Arbor, MI). *mer* gene sequences were entered in the blastn database to confirm gene

154 identity and identify similar sequences.

PCR amplification and sequencing of Tn*21* genes and antibiotic resistance genes.

156 Primers (Table 1) were used to amplify Tn*21*, class 1 integron genes, and the tetracycline

resistance gene Tet A. These reactions were carried out on a gradient thermocycler

158 (iCycler, BioRad Hercules, CA) for 35 cycles of 94 ^{o}C for 1 min, 53-57°C for 1 min and

72°C for 2.5 min. The 1 kb PCR product of *in-F* and *in-B*, the 1 kb Tet A amplicon, a 411

160 bp *tnpA* amplicon, and a 240 bp *tnpR* amplicon were sequenced

Conjugation experiments and plasmid profiling. The ability of *A. salmonicida* AS03

162 to transfer mercury- and antibiotic resistance genes to *E.coli* DH5α (Invitrogen Life

Technologies; Carlsbad, CA) was examined by conjugation experiments using the solid

164 plating medium method (21). Growing colonies of the *A. salmonicida* AS03 were mixed

with approximately equal amounts of growing recipient strain *E. coli* DH5α on BHI

166   plates, with mercury and antibiotic amendments as specified below, and incubated at

22°C from 1 to 2 days

168   The frequency of transfer was determined according to the method of Sorum, et

al. (37) with the following modifications. Transfer frequency was measured by dividing

170   the number of transconjugants per ml by the number of recipients per ml in the mating

mixture. The total number of recipients was estimated after overnight incubation on BHI

172   solid plating media without selection agents at 37°C, at which the growth of the donor

strain was suppressed, while selection of transconjugants was done on BHI agar plates

174   with either 8 μg ml^{-1} of chloramphenicol or 250 μM HgCl$_2$ following incubation at 37°C.

These concentrations of chloramphenicol and HgCl$_2$ were found to inhibit growth of the

176   *E. coli* DH5α recipient. All *E. coli* DH5α transconjugants were subjected to mercury and

antibiotic MIC assays at a temperature of 37°C to determine their phenotypic resistance

178   characteristics. The transfer frequencies were calculated on the basis of the average

number of colonies counted from duplicate plates after appropriate serial dilution (2.0

180   McFarland) of the mating mixture.

        Several conjugation experiments were performed to determine if the transfer of

182   resistance genes is stimulated by exposure of the donor *A. salmonicida* AS03 to mercury

and chloramphenicol. Three experiments were conducted under each condition of either

184   chloramphenicol or mercury exposure of the donor strain and mating mixture. To assess

the stability of the resistance determinants in the *E. coli* DH5α transconjugants, both

186   antibiotic and mercury MICs were done on the transconjugants after 10 subculture

passages on BHI plating media at 37°C.

188   **(i) Conjugation in the presence of chloramphenicol.** *A. salmonicida* AS03 was

grown overnight on BHI solid plating media amended with 8 μg ml^{-1} chloramphenicol.

190   Donor and recipient strains were mixed as described above on BHI agar plates containing

1 μg ml^{-1} chloramphenicol, a concentration determined to be sub-lethal to recipient *E.*

192   *coli* DH5α. The mating mixtures were incubated and the frequencies of transfer were

determined as described above.

194   **(ii) Conjugation in the presence of mercury.** The donor strain, *A salmonicida*

AS03, was grown overnight on BHI solid plating media with added 25 μM HgCl$_2$.

196   Donor and recipient strains were mixed as described above on BHI agar plates containing

25 μM HgCl$_2$, and the mating mixtures were incubated as described above. Transfer

198   frequencies were done as described above except that selection for *E. coli* DH5α

transconjugants was done on BHI plating media with 250 μM HgCl$_2$.

200   Plasmid DNA was isolated from *A. salmonicida* AS03, *E. coli* DH5α recipient,

and the *E. coli* DH5α transconjugant using the E.N.Z.A. Plasmid miniprep kit (Omega

202   Bio-tek, Doraville, GA). Plasmids were visualized using pulsed field gel electrophoresis

(PFGE) in a 0.8% agarose gel at 175 V at 4°C. Genomic DNA was extracted from *A.*

204   *salmonicida* AS03, *E. coli* DH5α recipient, and the *E. coli* DH5α transconjugant as

described above in order to serve as template DNA in the following PCR amplifications.

206   PCR primer sets A1-s.F and A5-n.R, *In-F* and *In-B*, tnpR-F and tnpR-B, Tet A FW and

Tet A RV, and p5-II and p2-II (Table 1) were used to probe the *E. coli* DH5α recipient

208   and transconjugant for the presence of the *merA*, *aadA7*, *tnpR*, Tet A, and *tnpA* genes that

were present in *A. salmonicida* ASO3.

210 **Nucleotide sequence accession numbers.** The sequence of the 16S rRNA gene has been

deposited in the GenBank database under the following accession number: strain AS03

212 XXXXXXXXX. Partial sequences of the *merA*, *merD*, *merR-T*, *merB*, Tet A, and *aadA7*

genes of strain AS03 have been deposited in the GenBank database under accession

214 numbers XXXXXX through XXXXXXX

232

Hg and Antibiotic minimum inhibitory concentrations of *A. salmonicida* AS03.

234   *Aeromonas salmonicida* AS03 demonstrated resistance to $\geq$1000 μM HgCl$_2$ and $\geq$32 μM

PMA as well as maximal resistance to 11 antimicrobials. In addition, some low-level

236   resistance to ceftriaxone, ciprofloxacin, ofloxacin, and trimethoprim/sulfamethoxazole

was observed (Table 2). Antimicrobial susceptibility disc assays showed that *A.*

238   *salmonicida* AS03 was also resistant to 10 μg streptomycin and 30 μg chloramphenicol,

and susceptible to 10 μg tobramycin and 30 μg kanamycin

240   **Genes encoding the *mer* operon.** Regions of the *merA*, *merB*, *merD*, *merR*, *merP*, and

merT genes were amplified and sequenced in *A. salmonicida* AS03. All *mer* gene PCR

242   amplifications of *A. salmonicida* AS03 produced single PCR bands of the following

expected sizes: 288 bp for *merA*, 134 bp for *merA-P*, 225 bp for *merR-T*, 502 bp for

244   *merB*, 219 bp for *merD*, and 181 bp for *merA-D*. Blastn searches confirmed the identities

of the amplicons. All genes demonstrated the most sequence similarity to *Klebsiella*

246   *pneumonaie* pRMH760 (>95% sequence similarity), which contains a pDU1358-like

mer locus (accession no. AY123253). PCR mapping of the *merD-merA* region verified

248   the presence of *merB* between *merA* and *merD* (3, 24, 25).

Antibiotic resistance genes. PCR amplification with class 1 integron primers *in-F* and

250   *in-B* yielded several amplicons in *A. salmonicida* AS03. A 1 kb amplicon from this

amplification was successfully sequenced and identified through blastn analysis as

252   *aadA7*, which encodes an aminoglycoside 3' adenyltransferase enzyme conferring

resistance to streptomycin and spectinomycin. This gene exhibited the most similarity to

254   *aadA7* in *Esherichia coli (*AF234167.1 *), Vibrio cholerae* (DQ196322.1) and *Salmonella*

enterica (AY463737) and explains the streptomycin resistant phenotype of *A.*

256   *salmonicida* AS03 determined by antimicrobial susceptibility disks. PCR primers *qacF*

and *sulR* yielded an approximately 800 bp PCR product which was identified by blastn

258   analysis on the reverse sequence as *sul1* This *sul1* gene resembled *sul1* genes of *E. coli*

plasmid PQR-1 (AY655485) and *K. pneumonaie* pRMH760 (AY123253). The forward

260   sequence confirmed the presence of *qacEΔ1* and was most similar to *qacEΔ1* in E. coli

pSa (L06822.4) and pRMH760 (AY123253) in the blastn database. PCR and gene

262   sequencing with primers *tetA FW* and *tetA RV* amplified an approximately 1 kb amplicon,

which demonstrated the most sequence similarity with *tetA* from multiple genera,

264   including *E. coli* pAPEC-OR-R (AY214164), *S. S. typhimurium* pU302L (AY333434),

and *A. salmonicida* pRAS1 (AJ131405).

266   **Transposon genes**. Because this strain exhibited simultaneous antibiotic and Hg

resistance phenotypes, the presence of Tn*21*, which carries both resistance determinants,

268   was assayed using primers described by Dahlberg et al. and Guerra et al.(6, 10). A 411 bp

fragment was amplified and sequenced using primers *p5-II* and *p2-II,* which was more

270   similar to the *tnpA* from Tn*1696* than that of *tnpA* of Tn*21,* and was almost identical to

the Tn*1696 tnpA* of *P. arguinosa* R1033 (U12338.2) and *K. pneumonaie* pRMH760

272   (AY123253). Similarly, the 240 bp amplicon obtained from PCR with primers *tnpR-R*

and *tnpR-F* was identified as *tnpR* from Tn*1696* and was near identical to the Tn*1696*

274   *tnpR* of *P. arguinosa* p1033 and *K. pneumonaie* pRMH760.

    Conjugation. *A. salmonicida* AS03 was able to transfer both mercury and antibiotic

276   resistance to *E. coli* DH5α in conjugation experiments. Initial conjugation experiments

showed that, regardless of the selective agent, either 8 μg ml^{-1}chloramphenicol or 250

278   μM HgCl$_2$, the *E. coli* DH5α transconjugant had multiple antibiotic resistances with MIC

levels either identical to or exceeding that of the donor *A. salmonicida* AS03 strain,

280   especially among the tetracycline, penicillin, and cephem classes of antibiotics (Table 2).

The folate pathway inhibitor sulfisoxizole was also expressed maximally in the

282   transconjugant. Notably, antibiotics of the fluoroquinolone class were not transferred,

even though the donor, *A. salmonicida* AS03, exhibited low levels of resistance to some

284   of the antimicrobials in both the fluoroquinolone classes.

         Similarly, mercury MICs in the transconjugant were identical under conditions of

286   either chloramphenicol or $HgCl_2$ selection. The donor *A. salmonicida* AS03 exhibited

high resistance to mercury with MICs of ≥ 1 mM $HgCl_2$ and ≥ 32 μM PMA, whereas the

288   *E. coli* DH5α recipient showed low levels of mercury resistance with MICs of 100 μM

$HgCl_2$ and 16 μM PMA. After mating with *A. salmonicida* AS03, the *E. coli* DH5α

290   transconjugant had mercury MICs of ≥ 1 mM $HgCl_2$ and ≥ 32 μM PMA. No plasmids

were isolated from the *E. coli* DH5α recipient nor the transconjugant, while at least

292   three plasmids, estimated to be between 4-10 kB using the BAC-Tracker Supercoiled

DNA Ladder (Epicentre, Madison, WI), were visualized in the *A. salmonicida* donor.

294   PCR amplification from the genomic DNA of the *E. coli* DH5α transconjugant showed

the presence of the *merA*, *aadA7*, *tnpR*, *Tet* A, and *tnpA* genes that were previously

296   sequenced in the *A. salmonicida* AS03 donor. These genes were not amplified in the *E.*

coli DH5α recipient and, therefore, must have been acquired by the *E. coli* DH5α

298   transconjugant via conjugative transfer from the *A. salmonicida* AS03 donor (Figure 1).

300
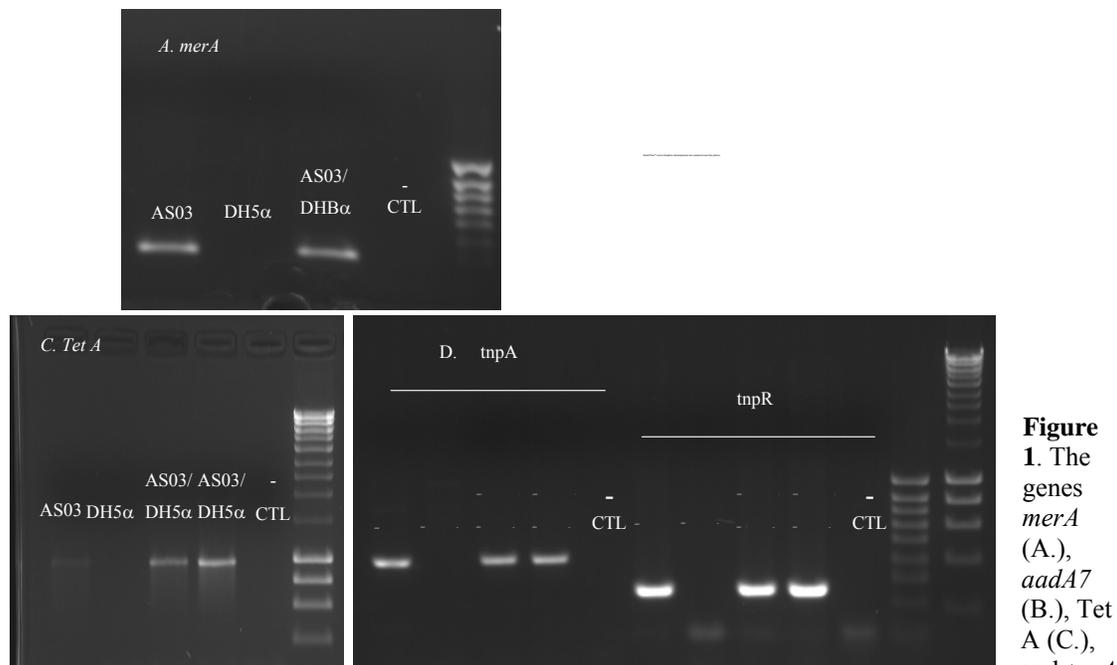

Figure 1. The genes *merA* (A.), *aadA7* (B.), Tet A (C.), and *tnpA*

326 and *tnpR* (D.) are present in the *A. salmonicida* AS03 donor and the *E. coli* DH5α transconjugant but absent
in the *E. coli* DH5α recipient, showing that these genes were transferred to the *E coli* DH5α transconjugant
328 from *A. salmonicida* AS03 via conjugation. The notation AS03/DH5α is used to denote the transconjugant
on the gel pictures.

330

332   Conjugative transfer of resistance determinants to the *E. coli* DH5α recipient

varied under different conditions of the donor and mating mixture. The highest transfer

334 frequencies were observed when the donor was grown on BHI plating media amended

with either 8 µg ml^{-1} chloramphenicol or 25 µM HgCl$_2$ prior to conjugation and the

336 mating mixtures contained either chloramphenicol or mercury at levels sub-lethal to the

E. coli DH5α recipient (1 µg ml^{-1} chloramphenicol or 25 µM HgCl$_2$). Statistically, there

338 was no significant difference between the transfer frequencies of these two exposure

conditions. However, exposure to either chloramphenicol or mercury stimulated

340 significantly greater transfer frequencies than observed in the control, which contained

neither mercury nor chloramphenicol (Table 3).   Regardless of the exposure condition,

342 transconjugants maintained the same mercury and antibiotic resistance phenotypes they

had demonstrated immediately after conjugation following ten sequential transfers on

344   BHI plating media, indicating that all of the transferred resistance determinants were

        stably inherited.

346

348   **Table 3**. Transfer frequencies of a conjugation between an *E. coli* DH5α recipient and an *A. salmonicida*
        AS03 donor on solid BHI media under different conditions

Conjugation Condition	Transfer Frequency [a] ± SE
BHI agar	$(2.20 \pm .48) \times 10^{-2}$
25 μM Hg in BHI agar	$(4.85 \pm .94) \times 10^{-2}$
8 μM Chloramphenicol in BHI agar	$(6.60 \pm 1.0) \times 10^{-2}$

350   [a] Transfer frequency is the number of CFU on selective BHI media containing 8 μg ml^{-1} chloramphenicol
        divided by the number of CFU on non-selective BHI media

352

Discussion

354   Hg resistance in *A. salmonicida* AS03 was found to be encoded by a broad-

        spectrum pDU1358-like *mer* operon. Plasmid pDU1358 is a multiple-antibiotic resistance

356   IncC incompatibility group plasmid, specifying broad-spectrum mercurial resistance, that

        was originally isolated from a hospital strain of *Serratia marcescens* (16) *A. salmonicida*

358   AS03 exhibited a similar amplicon pattern to that of pDU1358 locus 8 and a dissimilar

        pattern to that of Tn*21* based upon the results reported by Liebert et al.(25). Additionally,

360   the *mer* sequence in blastn with the highest degree of similarity to all *A. salmonicida mer*

        sequences, pRMH760, is a pDU1358-like *mer* locus. pRMH760 is a conjugative plasmid

362   that carries resistances to chloramphenicol, ampicillin, gentamicin, kanamycin,

        neomycin, streptomycin, spectinomycin, sulfamethoxazole, tobramycin, and

364   trimethoprim as well as a Tn*1696* transposition module and a broad-spectrum *mer*

        locus(32). The mobile genetic element in *A. salmonicida* AS03 was also shown to carry

366   ampicillin, streptomycin, spectinomycin, sulfamethoxazole, and trimethopim resistances

in addition to the broad-spectrum *mer* locus and Tn*1696* transposition module. Hence,

368   similar integron-containing composite transposons could be present in *A. salmonicida*

AS03 and pRMH760. Several gram-negative isolates have been reported to possess more

370   than one type of *mer* locus (25, 33). Data from this study does not support the existence

of more than one type of *mer* locus in *A. salmonicida* AS03. Whereas Liebert et al. (20)

372   found multiple mer loci in their bacterial isolates, as determined by the presence of

multiple PCR bands, using the same PCR primer pairs (B1 and B2, D2 and D3, P1 and

374   AO and R1 and A5), we observed only a single amplicon for the same PCR

amplifications in *A. salmonicida* AS03.

376   Class I integrons are prevalent in antibiotic-resistant clinical isolates of gram-

negative bacteria (32). Each class 1 integron may contain several gene cassettes

378   encoding antibiotic resistance, and the global reservoir for these cassettes is large (22,

27). Our data support the presence of at least one class 1 integron in *A. salmonicida*

380   AS03. The class 1 integron genes *sul1, qacEΔ1* and *aadA7* were sequenced from this

strain. The aminoglycoside resistance gene that encodes for adenyltransferase,

382   *aadA7*,was first found in an *E. coli* strain in which the *mer* operon was located on the

mobile genetic element Tn*21*(27). *aadA7* has never been reported in *A. salmonicida* (2,

384   12, 23, 27, 31). The tetracycline resistance gene, Tet A, has previously been found in *A.*

salmonicida, purportedly as a result of the widespread use of tetracycline in veterinary

386   medicine (22). This tetracycline resistance determinant was probed for in this study as

this gene has been found in many *A. salmonicida* strains and, along with Tet E, is the

388   most common tetracycline resistance determinant isolated from aquatic bacteria(21, 22)

The transposase genes *tnpA* and *tnpR* amplified and sequenced in this study show

390   a higher degree of similarity to these genes found on Tn*1696* than those carried on Tn*21*.

This transposition module has not previously been reported in *A. salmonicida*. However,

392   the integron In4, which is typically associated with Tn*1696*, has been detected in *A.

salmonicida* (36). It is possible that the *mer* operon and associated antibiotic resistance

394   genes in *A. salmonicida* AS03 are under the control of the Tn*1696* transposition module

as part of a composite transposon.

396   The conjugation data strongly indicate that the antibiotic resistance determinants

in *A. salmonicida* AS03, with the exception of those encoding resistance to

398   fluoroquinolones, the *mer* operon and Tn*1696* transposition module were located together

on a mobile genetic element capable of conjugative gene transfer. Supporting this

400   observation is the fact that, with the exception of fluoroquinolone resistance, the

antibiotic resistance determinants previously reported in *A. salmonicida* are encoded on

402   plasmids, in which resistance genes are often closely linked on mobile genetic

elements(22, 24, 27, 30, 43). The plasmid pRMH760 carries many of the same antibiotic

404   resistance determinants in addition to the *mer* operon and Tn*1696* transposition module

and these genes were similarly transferred to. *coli* DH5α (32). Multiple conjugation

406   experiments were conducted under different mating mixture conditions of

chloramphenicol and mercury exposure. However, all transconjugants exhibited identical

408   antibiotic and mercury resistance phenotypes (Table 2). These data strongly suggest that

these genes are located on a single mobile genetic element as opposed to multiple genetic

410   elements.

Because these resistance genes are transferable via conjugation, it is likely that the

412 mobile genetic element containing the *mer* operon, the Tn*1696* transposition module, and

the genes encoding the transferred antibiotic resistances is either a conjugative R plasmid

414 or conjugative transposon. Plasmids were not detected in either the *E. coli* DH5α

recipient or the transconjugant that had phenotypically similar mercury and antibiotic

416 resistance capabilities as the donor *A. salmonicida* AS03. The resistance genes could

either be present on a low-copy number plasmid that was not detectable by standard

418 experimental protocols or that they were located on a conjugative transposon that, after

conjugative transfer, integrated in the recipient's chromosome. Previous studies

420 involving conjugative transposons in various conjugation systems have reported the

inability to detect plasmids in the transconjugants (19) Due to the high levels of

422 antimicrobial and mercury resistance in the transconjugant, it would be expected that

plasmids containing these resistance determinants to be in high copy number. Therefore,

424 our data suggest that the mercury and antibiotic resistance genes, as well as the

transposition module of Tn*1696*, were encoded on a conjugative transposon. Conjugative

426 transposons are known to carry both mercury and antibiotic resistance genes. The

conjugative transposon SXT, characterized in *Vibrio cholerae*, encodes resistance to

428 sulfamethoxazole, trimethoprim, chloramphenicol, and streptomycin (20). In this study,

all of antibiotic genes encoded on SXT were observed to be transferable in our

430 conjugation system (Table 2).

Furthermore, it was demonstrated that low-level Hg and chloramphenicol can

432 stimulate conjugation as evidenced by increased the transfer frequencies (Table 3). Due

to atmospheric deposition, mercury levels in the environment are rising and its presence

434   in the landscape is a threat to wildlife as well as human health in the Northeastern United

States and Atlantic Canada (4, 14, 26, 39). High mercury levels have been documented in

436   freshwater and marine fish in Atlantic Canada and the United States and fish

consumption advisories have been issued in all five Canadian Provinces as well as thirty-

438   nine states in the U.S (7, 8, 13, 14). Our study provides evidence that environmental

mercury might have provided the direct selection pressure necessary to facilitate the

440   acquisition of broad-spectrum Hg resistance, as well as the indirect selection pressure that

facilitated multiple-drug resistance by *A. salmonicida* AS03. Due to Hg pollution, bodies

442   of water contain low-levels of Hg. Not only can this mercury continually select for the

presence of plasmids or transposons with mercury resistance genes but this mercury can

444   stimulate the transfer of these resistance genes between bacterial species. In addition,

antibiotic resistance genes were transferred to *E. coli* DH5α along with mercury

446   resistance genes in the complete absence of antibiotics and in the presence of low-level

mercury in the mating mixtures. This demonstrates that mercury can in fact directly select

448   for the transfer of mercury resistance genes and indirectly select for the horizontal

transfer of antibiotic resistance genes in a system in which the antibiotic and mercury

450   resistance genes are both located on mobile genetic elements. This potentially pathogenic

aeromonad is significant not only because it is resistant to many antibiotics but because

452   its antibiotic and mercury resistances are located on mobile genetic elements, which may

include conjugative R-plasmids or conjugative transposons, and can disseminate these

454   genes to other organisms by horizontal gene transfer. This genetic element can easily be

transferred to other bacterial strains, such as salmonid commensal bacteria or other

456   pathogenic hatchery bacteria when low-level Hg acts as a selection agent.
